SUMMARY
In the present study, to identify the clinical significance of the cytokeratin (CK) 20 staining pattern in Merkel cell carcinoma (MCC), we retrospectively analyzed the major clinicopathological and immunohistochemical characteristics of 12 cases of MCC. Typical dot-like pattern was seen in eight of our patients, while four patients showed peripheral staining pattern. Interestingly, all cases of MCC with dot-like CK20 tumor cells occurred in the head and neck region, while those with peripheral CK20 pattern tended to be located in other lesions (forearm, knee, or buttock): The difference of frequency in the head and neck regions was statistically significant. Dot-like CK20 staining pattern may therefore be resulted from ultraviolet exposure. Additionally, although without significance, metastasis was more frequent in those with dot-like CK20 than in peripheral CK20 staining: All patients with peripheral CK20 pattern had complete remission by surgical excision with or without radiation therapy. CK20 staining pattern may be a novel predictor of prognosis.

Keywords
Immunohistochemistry, skin, CK20

1. Introduction
Merkel cell carcinoma (MCC) is a rare and aggressive epithelial cutaneous neoplasm with neuroendocrine differentiation. It typically appears as solitary red-violaceous tumors in sun-exposed head and neck lesions of elderly people (1); it grows rapidly without pain. Males are more susceptible, and the mean age of patients is reported to be 70 years (2). Merkel cell polyomavirus is detected in 80% of the lesions. Histopathologically, the tumor typically consists of a dense population of small, round, and uniform cells in the dermis and subcutaneous tissue without change to the overlying epidermis. Differential diagnosis includes the “small round blue cell” tumor group, e.g., metastatic small cell carcinoma of the lung. Immunohistochemical analysis of cytokeratin (CK)20, epithelial membrane antigen, neuron-specific enolase, synaptophysin, chromogranin A, thyroid transcription factor (TTF)-1, S100 protein, leucocyte common antigen, and CD56 has been shown to be useful for the diagnosis (1).

CK20 staining of tumor cells shows perinuclear dot-like patterns in the majority of patients with MCC. Meanwhile, we recently noticed peripheral CK20 staining pattern in a patient subset. In this study, to identify the clinical significance of CK20 staining pattern, we retrospectively analyzed the major clinicopathological and immunohistochemical characteristics of patients with MCC.

2. Materials and Methods
2.1. Clinical assessment and patient material
The present study includes 12 patients with MCC (6 men and 6 women) who visited Wakayama Medical University Hospital between 2010 and 2020. All patients were diagnosed based on clinical manifestation and immunohistopathological findings. Patient data (age, gender, location, diameter of MCC, immunohistological findings, and prognosis) were collected retrospectively (Table 1).

2.2. CK20 immunoreactivity
Skin samples were paraffin-embedded, and sections were dewaxed in xylene and rehydrated in graded alcohols. Hematoxylin and eosin staining was performed as described previously (3).

For immunostaining, anti-cytokeratin 20 rabbit
monoclonal primary antibody (Roche Diagnostics, Indiana, USA) was optimized for use with VENTANA OptiView DAB IHC Detection Kit (Ventana medical system, Arizona, USA) on automated VENTANA BenchMark ULTRA platform (Roche Diagnostics). CK20-positive cells were randomly observed in five different 800-fold magnification fields under the inverted microscope. Dominant staining patterns were recorded.

2.3. Statistical analysis

Statistical analysis was carried out with Fisher’s exact test to compare frequency. P values < 0.05 were considered significant.

3. Results and Discussion

3.1. Clinical and histopathological features of MCC patients

We collected the clinical data of 12 patients with MCC for the present study. Detail of one of the patients (case No.3) was previously published as case report focusing on reconstruction surgery (4).

As shown in Table 1, the clinical characteristics of 12 lesions were as follows: mean age was 82.1 years (age range: 75-89 years), and male:female ratio was 6:6. Distribution of the tumors was 3 lesions in the cheeks, 2 in the eyelids, 1 in the external canthus, 3 in the earlobes, 1 in the forearm, 1 in the lower leg, and 1 in the buttock. The mean diameter of the tumors was 2.6 cm (range: 1-5 cm). Regarding the immunoreactivity of the tumor cells, staining of CK20 was positive in all cases. CD56 was also positive in all seven tested cases. Positive staining of synaptophysin or chromogranin A, the most common neuroendocrine markers, was also observed in eight out of the nine tested cases. None of the cases tested were positive for CK7 or TTF-1 (0/7 and 0/9, respectively). Merkel cell polyomavirus was detected in three cases.

These clinical and immunohistopathological features are generally consistent with previous notions (2). We noticed, however, that there are two different CK20 patterns of tumor cell immunoreactivity: typical dot-like pattern, a perinuclear globular aggregation, was seen in eight cases, while four cases showed peripheral staining patterns. Representative clinical and histopathological findings of cases with dot-like pattern and those with peripheral pattern are shown in Figures 1 and 2, respectively.

3.2. Clinical significance of different CK20 immunoreactivity of tumor cells

We then attempted to identify the clinical significance of different CK20 immunoreactivity of tumor cells. There

Table 1. Summary of clinical and histopathological features of our patients
significant (100.0% vs. 25.0%, \( p = 0.0182 \) by Fisher Exact test).

In addition, although insignificant, metastasis was more frequent in those with dot-like CK20 (50.0% vs. 0.0%, \( p = 0.21 \)) than peripheral CK20 staining; all patients with peripheral CK20 pattern resulted in complete remission by surgical excision with or was no statistically significant correlation with age, gender, location, or diameter of the tumors. However, all of the MCCs with dot-like CK20 tumor cells occurred in the head and neck region, while those with peripheral CK20 pattern tended to be located in other lesions (forearm, knee, or buttock), and the difference of frequency in head and neck lesions was statistically significant (100.0% vs. 25.0%, \( p = 0.0182 \) by Fisher Exact test).

In addition, although insignificant, metastasis was more frequent in those with dot-like CK20 (50.0% vs. 0.0%, \( p = 0.21 \)) than peripheral CK20 staining; all patients with peripheral CK20 pattern resulted in complete remission by surgical excision with or
without radiation therapy. There was no difference in the positivity of other immunostaining between the two groups.

CK20 is a type I cytokeratin, which is a major cellular protein of mature enterocytes and goblet cells. CK20 expression is usually therefore observed in normal gastric and intestinal mucosa (5), and CK20 staining is used to identify a range of adenocarcinoma arising from CK20-positive epithelia, including colorectal cancer. In addition, tumor cells of MCC are well known to express CK20, but are absent in metastatic lung cancer.

CK20 staining pattern of enterocytes is usually diffuse, while dot-like perinuclear pattern was characteristic of the tumor cells of MCC (6,7). To our knowledge, the mechanism of dot-like CK20 staining, however, remains unknown. Furthermore, we noticed peripheral staining pattern of CK20 in a subset of MCC patients. We found that all MCCs with dot-like CK20 tumor cells occurred in the head and neck region, while those with peripheral pattern CK20 tended to be located in the trunk and extremities, and the difference was statistically significant. Established risk factors for MCC are immunosuppression and extensive sun exposure: increased frequency of MCCs in patients with acquired immune deficiency syndrome and in those receiving immunosuppressive therapy has been reported (7). The incidence rate of cutaneous MCC is also increased by sun exposure (7). Here, all MCCs with dot-like CK20 tumor cells occurred in the head and neck region, so dot-like CK20 staining pattern may be the result of ultraviolet exposure. There has been quite a few report to focus on the staining pattern of CK20 in patients with MCC.

Metastasis was more frequent in patients with dot-like CK20 than in peripheral CK20 staining, whereas all patients with peripheral CK20 pattern resulted in complete remission by surgical excision with or without radiation. The rates of local and regional recurrence were reported to be 29% and 59%, respectively, in MCC patients (7). In addition, the estimated mortality rate for all patients with MCC is between 25% and 35% (8). Previous studies reported poor prognostic factors to be male sex, tumor size > 5 mm or > 20 mm, location (in the buttock/thigh/trunk or in the head), advanced clinical stage, small cell size, high mitotic index, diffuse growth pattern, as well as p53 positivity (9). CK20 staining pattern may also be a novel predictor of prognosis in MCC. Detailed research with a larger number of samples is necessary to prove clinical significance of CK20 staining pattern.
